Conference on Developing Quantitative Marxism April 2008, University of Bristol

Simulating extended reproduction

Poverty reduction and class dynamics in Bolivia

Jorge Buzaglo a and Alvaro Calzadilla

ABSTRACT:

Dynamic input-output can be seen (Oskar Lange, András Bródy) as a development of Marx's extended reproduction model. Solution of an empirical dynamic input-output system typically gives the (equal, constant) growth rates of sectoral outputs, at long run, equilibrium proportions. In policy oriented applications, a more flexible, simulation approach may be useful. Our model responds to the need of evaluating the effects of alternative poverty reduction strategies. Three policy variables are introduced, namely, (de)indebtedness policy, investment policy and income distribution policy, contributing respectively to the objectives of policy autonomy, structural change and social justice. The Millennium Development Goal of halving extreme poverty by 2015 seems to be a difficult, but attainable goal for Bolivia. Given the expected debt reduction agreed with international creditors, the goal can be attained by a combination of investment and redistribution policies. The model shows also the effects of poverty reduction strategies on the different social classes.

It is generally taken for granted that Marxian economics and recent achievements in mathematical economics with large-scale digital computation are worlds apart. Certainly this need not be the case.

András Bródy (1970, p. 163)

1. Introduction

In his Preface to Bródy's (1970) book, Wassily Leontief holds that economics does not progress in a straight line, as a typical natural science does. Economic thought advances in curves and loops, like a broad river slowly winding its way across a flat plain. It turns left and right and divides from time to time into separate branches, some of which end up in stagnant pools, while others unite again into a single stream.

About three decades ago, the mainstream of economics briskly turned right, to enter the intellectual topography characteristic of long-period depression. It entered the rather sterile landscape of commodity and market fetishism. 'Egonomics' could this broad branch of the river more properly be called, based as it is on the constricted perspective of the *homunculus oeconomicus*. After traversing the dark valley of the long depressive phase, it seems to have ended up in a big, stagnant pool, incapable of giving meaningful answers to the many problems of senile, global capitalism. The several beaches on the sides of the pool — such as 'monetarism,' 'supply side economics,' and other variants of the neo-liberal/neo-conservative credo — are rapidly becoming out of fashion and deserted.

The Marxian branches of the river almost disappeared under the ground that was opened as a result of the powerful seismic movements of the period. They were obliged to follow difficult and rocky underground ways that hopefully purified and clarified them. Similar fates corresponded to close standing branches, such as neo-Ricardian, neo-Keynesian and neo-structuralist economics. Will these branches be able to surface again? Along with the new branch of ecological economics, will they unite into a single lively stream, as in Leontief's metaphor? Will they exploit the achievements in mathematical economics and the huge advances in digital computation, as Bródy suggested? Is the present Conference on Developing Quantitative Marxism a sign that it is so?

The model constructed for the present study responds to real and urgent needs — how to reduce poverty in a poor country. It was not intended as a contribution to Marxian economics, but as an approximation to the analysis of a particular, highly relevant problem. What is interesting with Marxian economics is that the most meaningful and useful analytical instrument to approach the problem of fighting poverty that can be found, was already drafted by Marx. The choice of the theoretical structure of our study was not the consequence of an ideological *parti pris*, but the result of the strict application of the scientific method — the choice of the best available method of analysis applicable to a concrete set of observations in order to obtain testable deductions. As we see it, this is *scientific socialism*, in the sense of putting reason and science in the service of the free flourishing of human being and human society.

The source of the approach is Marx's reproduction schemes. As we show below, Marx's approach was refined by several authors, before getting its most developed form from Leontief. Yet only Marxist authors such as Lange and Bródy dared to refer to the apparent Marxian roots of input-output analysis. Most others preferred not to be associated with such a heretic. Quesnay and Walras were more presentable forefathers — even if Walras cannot honestly be associated with the approach.

Our reproduction simulation model is, like the dynamic input-output model, a disaggregated 'Harrod-Domar model.' Growth depends on the magnitude of social surplus (saving) and the effectiveness of investment (incremental capital output ratios). What principally distinguishes the model from the dynamic input-output model is the character of the solution. The solution of the dynamic input-output model gives the uniform, equiproportional rate of expansion for all sectors of the economy, and the output composition consistent with that rate of growth. This solution can be understood as the ideal, inherent expansion capabilities and equilibrium proportions belonging to the technological infrastructure (input and capital matrices) of the economy, for given distributional structures and saving/consumption behaviours.

The simulation approach is an applied, policy oriented approach. It departs from conditions existing at the start of the period of analysis, i.e. initial output levels and proportions. It studies different policies, which result in different output growth trajectories, given initial conditions, and given technologies and behaviours in the economy. A key policy variable is investment policy, which influences structural change in the economy. Another important policy variable, which affects the degree of policy autonomy, is the level of foreign indebtedness, or accumulated foreign savings. The third key policy element is income distribution policy, particularly crucial in the context of highly unequal economies. The degree of distributive equity or social justice directly affects the poverty rate, whose reduction is the main focus of our study.

The frame of our strategy simulations is the UN Millennium Development Goal of halving extreme poverty by 2015. Different output trajectories result in different rates of poverty reduction. A status quo investment policy of maintaining the past emphasis in natural resource production and export is less effective in reducing poverty than a policy which tries to generate poverty minimising output trajectories. Our study also shows that a policy which stimulates increasing employment is very similar in its effects to a poverty minimising policy.

Given in Bolivia a very high poverty rate of 70 percent of the population and a very unequal income distribution, changes in the structure of output are not sufficient for achieving the Millennium Goal. The study shows what are the minimal income redistribution efforts, which in addition to pro-poor structural change are necessary in order to halve extreme poverty by 2015. A more advanced redistribution policy is also simulated, which totally eliminates extreme poverty.

The poorest country in South America, with an average income not much above the poverty line of 2 dollars a day, all social classes are more or less affected by poverty in Bolivia. But capitalists, workers and peasants benefit differently from different strategies. Status quo tends to benefit high income classes, and redistribution policies benefit low income classes. Dualism and heterogeneity in the economy — and possibly also statistical limitations — give rise to some counterintuitive results, such as for instance that the workers do not directly benefit of poverty reducing policies.

These are main themes of the following sections.

2. Reproduction schemes and input-output analysis

A permanent trait of the classical theory of economic growth, from Quesnay to Marx, is the idea that the expansion of societies' product depends on investment of the non consumed surplus product. There is growth when the product of society's work is more than what is necessary to satisfy consumption needs, and when this social surplus output takes the form of increased means of production put to work with increased labour force. Two central ideas are then, that total output must be larger than consumption — that is, positive surplus product or savings —, and that surplus product increases the existing means of production — that is, it is productively invested.

Quesnay's *Tableau Économique* (1766) was, in the words of Marx, 'the first systematic conception of capitalistic production' — 'an attempt to portray the whole production process of capital as a *process of reproduction*' — 'the most brilliant idea of which political economy had hitherto been guilty' (1963, p. 344). The *Tableau* models the circular flow among of the three main social classes of the incipient capitalism of the time — peasants, manufacturers/merchants and landlords — and the interdependence between income and expenditure in consumption and production. At the same time, the classes represent different sectors of economic activity. Quesnay refers to the sequence surplus-investment-growth in other writings, but the *Tableau* depicts an economy in simple reproduction, or stationary equilibrium.¹

Marx's analysis of reproduction establishes the conditions for equilibrium in an economy with two sectors (producing means of production and consumption goods) and two social classes,

_

¹ Eagly (1969) constructs a dynamic version of the *Tableau*.

capitalists and workers. The steady reproduction of the circular flow of the economy requires that the components of the social output — that is, used means of production and labour power, and surplus — keep definite proportions. In particular, the output of the sector producing means of production must equal the use (demand) of means of production by both sectors. In an expanding economy not all the surplus is consumed; part of the surplus is employed in increasing the amount of labour and means of production. These conditions can be interpreted as input-output equations, which result in particular conditions of equilibrium between the two departments.

For Marx, the importance of the reproduction schemes rests not only in the intersectoral consistency of equilibrium quantities, but also in the general framework required for a coherent determination of labour values and production prices. As shown by Kurz and Salvadori (2000), after Marx, the most important roots of input-output analysis are to be found in the works of authors investigating the determination of values and/or production prices within a complete representation of the circular flow of the economy as an interrelated system. Among the most important they include Dmitriev, Bortkiewicz and Charasoff.²

Another important source, not too often recalled today, is the attempt to construct a 'national economic balance' in the Soviet Union of the 1920s. This intended tool of planning for industrialisation and growth, was an explicit empirical implementation of the ideas underlying the reproduction schemes of Marx.³ Still a student at Leningrad University, Leontief wrote about this work in 1925:

What is essentially new in this balance ... is the attempt to embrace in figures not only the output but also the distribution of the national product, so as to obtain in this way a comprehensive picture of the whole process of reproduction in the form of a kind of 'Tableau Économique'.⁴

For authors cognizant of the Marxian tradition, such as Oskar Lange and András Bródy, it was easy too see the direct connexion between Marx's reproduction schemes and Leontief's input-output models. For Lange (1969, p. 47),

[t]he structure of production input equations ... is the same as that of Marx's schemes... It can be seen that the production input equations are an extension of the division of the Marxian schemes into n branches. Or also

Marx put forward the general idea that a balanced exchange of products among the various subdivisions of the national economy was essential if the processes of production and reproduction were to continue smoothly; in input-output analysis this idea is applied to the relationships arising among a large number of sectors of the national economy. (Lange, 1964, p. 192)

2. 1. Simple reproduction

_

² An interesting detail is that von Bortkiewicz was Leontief's dissertation adviser at Berlin University in the 1920s (Kurz and Salvadori, 2000, p. 169).

³ According to Jasny (1962), the idea was fathered by V.G.Groman, who produced the first draft of a balance of the national economy in 1923 at the Gosplan. Stalin thought this kind of work was 'a game with figures' (see references in Spulber and Dadkhah, 1975). 'The task which Groman had thought could have been accomplished in a matter of several weeks was ultimately done 38 years later. Early in 1961 Soviet statisticians completed "The Interbranch Balance of Production and Distribution of Output in the National Economy of the USSR for 1959" ... The speed of accomplishment is certainly amazing.' (Jasny, 1962, p. 79)

⁴ Weltwirtschaftliches Archiv, October 1925 (Jasny, 1962, p. 79).

With the powerful tools of the eigenvalue matrix algebra and Leontief's input-output representation, Bródy (1970) achieves a most compact and lucid formulation of the theory of reproduction.

Given the matrix A of input coefficients (denoting amounts of product i used to produce one unit of product j), and vectors v representing the inputs of labour force and c consumption needs, we can form (Bródy, 1970, p. 23) the "complete" matrix A:

$$\mathbf{A} = \begin{bmatrix} A & c \\ v & 0 \end{bmatrix}. \tag{1}$$

The economy is in simple reproduction when outputs \mathbf{x} are just enough to cover (intermediate and final) consumption needs:

$$\mathbf{A}\mathbf{x} = \mathbf{x}.\tag{2}$$

This is the same as saying that the maximal eigenvalue of matrix **A** is equal to one. That is, given the matrix **A**, and asked which are the scalars α (eigenvalues) and vectors **x** (eigenvectors) that satisfy the eigenequation $\mathbf{A}\mathbf{x} = \alpha \mathbf{x}$, we find in simple reproduction that the maximal eigenvalue $\alpha = 1.$

The gross output vector \mathbf{x} , as an eigenvector, gives only the proportions which satisfy the eigenequation $\mathbf{A}\mathbf{x} = \alpha \mathbf{x}$ — any scalar multiple of \mathbf{x} is also an eigenvector; only output proportions are determined by \mathbf{A} , not the absolute scale of production.

2.2. Extended reproduction

In simple reproduction then, final and intermediate consumption Ax equal total output x — no surplus is left. Extended reproduction is possible when not all output is consumed, when Ax < x; that is, when there is a positive surplus product in every sector: x - Ax = (I - A)x > 0. Each sector of the economy produces a positive surplus.

Output growth depends on surplus being invested in expanding productive capacities. A matrix \mathbf{B} is introduced, its coefficients indicating the quantity of output of sector i which must be invested in sector j in order to increase by one unit sector j's output in the next period.

Balanced expanded reproduction requires that the surplus products of the different production sectors on the left hand of equation (3) match the investment needs generated by the uniform rate of growth λ on the right hand:

$$(\mathbf{I} - \mathbf{A}) \mathbf{x} = \lambda \mathbf{B} \mathbf{x}, \tag{3}$$

that is, output should be so structured as to make possible a balanced growth in all sectors. Or also, if we write this as

$$\mathbf{x} = \mathbf{A}\mathbf{x} + \lambda \, \mathbf{B}\mathbf{x},\tag{4}$$

output supplies \mathbf{x} equal consumption plus investment demands associated with growth at the rate λ .

⁵ The eigenequation $\mathbf{A}\mathbf{x} = \alpha \mathbf{x}$ may also be written: $\alpha \mathbf{x} - \mathbf{A}\mathbf{x} = (\alpha \mathbf{I} - \mathbf{A}) \mathbf{x} = 0$. The eigenvalues are those values, α , that make the determinant of the matrix $(\alpha \mathbf{I} - \mathbf{A})$ singular. The determinant is an equation of degree n in α , with n, not necessarily distinct roots, associated with their respective eigenvectors (for more details see e.g. Bródy, 1970, Appendix I, or Wilkinson, 1965).

The solution of this equation for x gives output proportions that, after covering (intermediate and final) consumption Ax for simple reproduction, allow for growth in every sector at rate λ .

Bródy (1970, p. 47) shows that the numerical examples of extended reproduction set out in the second volume of Capital are based on the same assumptions as those implicit in equation (4). The ideas underlying this model and those expressed in Marx's schemata are the same — they are an extension to *n* sectors of the extended reproduction scheme.

2.3. Extended reproduction and the Harrod-Domar equation

Several authors have seen Marx's expanded reproduction scheme as the original source of the Harrod-Domar type of growth model. Bródy (1970, p. 100) shows this in a very straightforward manner, by defining production prices within the expanding reproduction system of equation (4).⁷

Prices of production are those prices \mathbf{p} which cover input and labour costs \mathbf{pA} , plus an average rate of profit λ on capital invested \mathbf{pB} :

$$\mathbf{p} = \mathbf{p}\mathbf{A} + \lambda \mathbf{p}\mathbf{B} \qquad .$$

If we now express equation (3) of expanded replication using the price system and the output structure which correspond to the balanced solution eigenvectors, we will have:

$$p(I - A) x = \lambda pBx.$$
 (6)

The rate of growth (and profit) λ can thus be expressed as the net product of society divided by total capital employed:

$$\lambda = \mathbf{p}(\mathbf{I} - \mathbf{A}) \times / \mathbf{pBx}. \tag{7}$$

Multiplying numerator and denominator by the total value of production **px**, we get:

$$\lambda = [\mathbf{p}(\mathbf{I} - \mathbf{A}) \times / \mathbf{p} \times \mathbf{x}] \cdot [\mathbf{p} \times / \mathbf{p} \times \mathbf{B} \times \mathbf{x}]$$
 (8)

in which the first factor is the saving ratio, and the second factor is what Bródy calls "capital productivity," the reciprocal of the capital/output ratio. This is the Harrod-Domar growth equation.

In his illuminating article of 1957 Lange arrived, with a different (more constructivist) mathematical approach, to the same conclusion: "... the rate of increase of gross national product is the product of the overall rate of investment and of the average output-outlay ratio" (Lange, 1964, p. 217). Lange's "output-outlay ratios" indicate the effect of a unit increase in investment outlay in the various sectors of the economy on national gross output.

7

⁶ The corresponding eigenequation now is: $[I/λ - (I - A)^{-1}B] x = 0$. The viable growth rate λ is (the reciprocal of) the maximal eigenvalue of the matrix $(I - A)^{-1}B$, to which corresponds a positive eigenvector x. Bródy (1970, p. 113) calls this solution 'stationary state'— it is also called 'turnpike' or 'von Neumann path.'

⁷ For Bródy, the main points of the Harrod-Domar model were already implicit in Kalecki's theory of the business cycle dating from the early 1930s, and also in the Soviet economist Feldmann's two-sector models from the 1920s.

⁸ The eigenequation of this system is : $\mathbf{p} \left[\mathbf{I} - \lambda \mathbf{B} \left(\mathbf{I} - \mathbf{A} \right)^{-1} \right] = \mathbf{0}$.

3. A simulation model for extended reproduction

Bródy (1970, p. 112) recognised the lack of realism of a solution giving a uniform expansion rate with fixed output proportions as one of the major limitations of the dynamic input-output model. However, a general solution of the eigenequation for a given economy, that is, a solution for the prices, output structure and rates of growth and profit that correspond to a long run, closed, balanced growth path may give many interesting insights.⁹

In practical application, however, in particular when analysing policies for growth and poverty reduction, a different solution approach seems necessary. Instead of defining optimal output structures for a closed economy, our approach is to start from existing outputs in an open economy, and to look at the effects of different output trajectories resulting from different investment patterns. That is, we adopt the simulation approach. Optimisation enters the picture when we attempt to select the output trajectory that maximises certain objective, e.g. poverty reduction.

Two other differences of our model refer to the inclusion of foreign saving and debt, and income distribution. The model reflects the possibility of enlarging the economy's saving and investment capacity by borrowing from abroad (i.e. by increasing foreign indebtedness) — or also the possibility of augmenting economic policy autonomy by reducing external indebtedness, along with the conditionalities imposed by foreign creditors.

The model includes also a detailed representation of income distribution and consumption/saving. Vector v representing inputs of labour force and vector c describing consumption in equation (1) are disaggregated by income level and social class, in order to trace the effects of alternative strategies on saving, consumption, investment and growth.

3.1. *The equation of extended reproduction: the dynamic link*

As shown above, expanded input-output reproduction can be seen as a disaggregated Harrod-Domar model, in which growth depends on average capital output ratios and total saving. As shown in equation (8), the growth rate equals the output capital ratio times the saving ratio. Or, multiplying by output, the increment of output equals the output capital ratio times savings.

Accordingly, the equation of motion of the model is:

$$x_{t+1} - x_t = \hat{\alpha}^{-1} d_t. {9}$$

That is, the increment of sectoral outputs x_t (an *n*-vector) equal their respective sector's incremental capital output ratios $\hat{\alpha}$ (a diagonal *n*-matrix), times the sectoral investments d_t (an *n*-vector).

Writing this as:
$$x_{t+1} = \hat{\alpha}^{-1} d_t + x_t \tag{10}$$

we see that the time-path of sectoral outputs depends on the (inverses of) sectoral incremental capital output ratios and sectoral investments. (The inverse elements $\hat{\alpha}^{-1}$ reflect sectoral output responses to investment; we will call them "investment efficiency coefficients.") In the words of Lange (1964, p. 269): "The investment done in one period adds to the amount of

⁹ See e.g. Bródy (1970, Part 3) on USA and Hungary and Tsukui and Murakami (1979) on Japan.

means of production in operation in the next period. In consequence, a larger output is obtained in the next period. The outputs of successive periods are linked up in a chain through the investments undertaken in each period. Thus, productive investment generates a process of growth of output."

The process follows the simple logic illustrated in Figure 1.

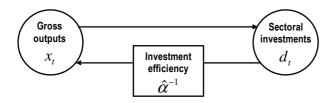

Fig. 1. Flow diagram of the dynamic law of the model

We can now introduce our first policy instrument, *investment policy*. Investment policy is the policy instrument which allows for influencing sectoral growth and output structure.

In order to specify an investment policy in the model of equation (9), let us distinguish between private investments d_t^p , and public investment d_t^g , of which sectoral investment d_t^g is the sum. Total investment equals total savings, and we assume for simplicity that the overall equality between savings and investment also applies for the private and public sector taken separately. Then, in the context of the model, given endogenously determined public saving s_t^g (a scalar), public investment is determined by investment policy:

$$d^{g}_{t} = z^{g}_{t} \, s^{g^{*}}_{t}, \tag{10}$$

where z^g_t is a distribution vector of public investment allocation shares. An *investment policy* is a time sequence $\{z^g_t\}$ of public investment allocation shares. A $\{z^g_t\}$ sequence can be exogenously given, as for instance in a historical simulation, or when some exogenously stipulated policy is tested. A $\{z^g_t\}$ sequence can be also determined by optimisation of some expression of social welfare — e.g. minimisation of the share of the poor in year 2015.

We see then that we are postulating the possibility of any allocation of investment — we are not trying to find balanced output paths as in expanded reproduction (equation (3)), in which investment demands must be satisfyied by domestic outputs. We assume an open economy, where excess demands and supplies can be internationally traded — e.g. excess supplies of oil can be exported, and excess demands of investment goods can be imported. (We are now describing sectoral supplies; sectoral demands will ve described in short.)

Also, private investment behaviour differs from Marx's schemes, where capitalists invest in their own sector. In the present model, capitalists allocate investments — that is, available saving/investment funds — according to the different sectors' past growth and their respective

¹⁰ Public investment is defined in a very wide sense, as the cost for the public sector of productivity-increasing changes. Public investment includes investments in infrastructure and public and mixed enterprises, and also the costs of explicit or implicit subsidisation of private investment (such as the different forms of 'industrial policy'). Theoretically, it should also include investment in the social sectors ('human capital'), and in research, but this is difficult to implement statistically.

capital density. In the following equation, private investments, d^p_t , equal private savings $s^{p^*}_t$, endogenously allocated according to the so called accelerator function z^p_t :

$$d^{p}_{t} = z^{p}_{t} s^{p*}_{t}, (11)$$

in which

$$z^{p}_{t} = \frac{\hat{\alpha}(x_{t} - x_{t-1})}{t'\hat{\alpha}(x_{t} - x_{t-1})},$$
(12)

where t is a summing vector (1,1,...,1). That is, total private savings are allocated according to past growth and capital/output ratios in the sector. ¹¹

3.2. Income distribution

We have thus far described the investment of private and public savings and their effects on output growth, given investment efficiency parameters, as shown in the lower and left sides of Fig. 2. Let us now complete the loop, describing how savings are determined from incomes generated in production, for given income distribution and savings coefficients, as shown in the upper and right sides of the figure.

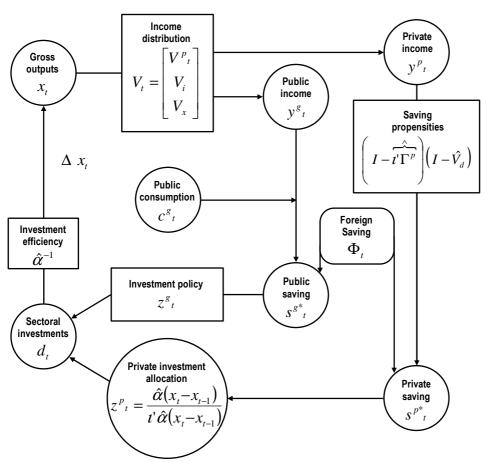

Fig. 2. Flow diagram of the dynamic core of the model

In the simplest form of reproduction analysis workers receive subsistence wages, and capitalists appropriate all surplus value or profits. In standard input-output, and even in the more elaborated analyses of Lange and Bródy the structure of income distribution is not

¹¹ The estimated function is a distributed accelerator including three previous periods, see Appendix A, eq.(11).

specified. Within the input–output framework, however, a quite natural extension is to assume income distribution coefficients analogue to production input coefficients, thus generalizing to the distribution of value added the proportionality assumption made in relation to production inputs. Inspired by Kaldor (1956), Miyasawa and Masegi (1963) introduced this approach, and defined sectoral income distribution coefficients by income class (e.g. capitalists and workers), with particular consumption and saving behaviors. ¹²

In line with this approach, the y_t vector of incomes of the k income classes, plus the government, plus external production factors depends linearly on sectoral gross outputs x_t :

$$y_t = V_t \ x_t, \tag{13}$$

in which V_t is a $(k+2)\times n$ matrix of shares of income (value added) by income class (plus the government and external factors), specific to each production sector. The V_t matrix is composed of a $(k\times n)$ V_t^p matrix of private incomes, an $(1\times n)$ V_t matrix of sectoral coefficients of indirect taxes and operating surplus of domestic enterprises, and an $(1\times n)$ V_x matrix of net flows of private external factors.

The model thus directly distributes value added generated in production among households, the government and the rest of the world — a simplification of the usual social accounting matrix (SAM) framework, in which the distribution among "factors of production" and institutions (firms, government, etc.) is also included. ¹⁴

The V^p_t matrix of sectoral income distribution may assume different specifications. The Kaldor-Miyasawa-Masegi specification analyses the sectoral distribution of income among *social classes*. Analysis of poverty and poverty reduction policy also requires a representation of the *size* distribution of incomes. Unless defined very narrowly, a socioeconomic classs may include both poor and non-poor households. Thus, a $(100 \times n)$ matrix V^p_t is defined, describing sectoral income shares by percentiles. The $(100 \times n)$ table:

$$V_{w}^{c} x_{t} \tag{14}$$

depicts the distribution of incomes by percentiles in each sector, with its cells showing total incomes by sector and percentile. Given the expected (total and sectoral) population over time, per capita sectoral incomes by percentiles are obtained. For a given poverty line income y_{pline} (a scalar), the sum of persons belonging to cells with *per capita* incomes below of the poverty line gives the number of the poor in period t.

¹³ In addition to indirect taxes and operating surpluses, the public sector's income includes import duties, transaction taxes (and other indirect taxes), direct taxes, net unilateral transfers and net debt service (see equation (2) in Appendix A).

¹² Batey and Rose (1998) survey the literature on this class of 'extended input-output models.'

Appendix C shows the structure of the simplified SAM of the model, and the SAM generated by the model for the initial year 2000 (the model generates SAMs for every year of the simulation). See Round (2003) for a survey of SAM literature, an approach closely related to extended input-output.

¹⁵ See eqs. 24-30, Appendix A, on the determination of population, sectoral employment, per capita incomes, and poverty measures.

The second policy dimension of the model, in addition to investment policy, is *income* distribution policy. In the context of the present model, an income distribution policy is a sequence $\{V_t\}$ of income distribution matrices. In Section 4.3, for example, we solve for an income distribution policy satisfying the Millennium Goal of halving extreme poverty by 2015.

3.3. Saving and consumption

Let us now close the loop of Figure 2, briefly describing the determination of saving and consumption from incomes generated in production.

Our representation of consumption and saving behaviour is already present in Lange's (1964) pathbreaking analysis. Lange introduces (p. 207) demand equations, based in behavioural data, which relate final consumption by produced item to value added. But while in Lange saving/investment is an exogenously determined share of total income, in the present model domestic savings are endogenously determined, non-consumed incomes. Economic policy can still influence the rate of investment by influencing income distribution policy $\{V_t\}$ — in particular, the share of public income in total income. This possibility is not tried in the present study.

Public savings (a scalar) is defined as the difference between public income and public consumption:

$$s^g{}_t = y^g{}_t - c^g{}_t. \tag{15}$$

In order to determine private savings, let us first define private consumption by type of output:

$$c^{p}_{t} = \Gamma^{p} \left(I - \hat{V}_{d} \right) y^{p}_{t}, \tag{16}$$

where c^p_t is an *n*-vector of consumption demands, Γ^p is an $(n \times k)$ matrix of consumption propensities, V_d is a $(1 \times n)$ matrix of coefficients of direct taxes and I is the identity matrix.

Private consumption demands by income class (a k-vector) are:

$$c^{p^*}{}_t = \widehat{\iota'} \widehat{\Gamma^p} \left(I - \widehat{V_d} \right) y^p{}_t,$$

in which t is a $(n \times 1)$ summing vector (1, 1, ..., 1)' and $t'\Gamma^p$ a $(k \times k)$ diagonal matrix of total consumption propensities by income class.

Hence, private savings by income class (a k-vector) are:

$$s^{p}_{t} = \left(I - \overrightarrow{\iota' \Gamma^{p}}\right) \left(I - \widehat{V}_{d}\right) y^{p}_{t}. \tag{17}$$

Our third policy dimension, along with investment and distribution policies, is foreign saving and indebtedness. The rate of net inflow of foreign capital, which adds to external indebtedness, is an exogenous variable in the context of the model. It may be understood as a policy variable, which works through policies related to international capital flows and currency exchange. The level of external indebtedness reflects the economy's degree of policy autonomy, as highly indebted countries are constrained in their policy choices by external creditors' policy preferences.

Exogenously determined (negative or positive) net foreign savings Φ_t added to private and public saving (for simplicity, at an equal rate), thus increasing (or decreasing) the volume of resources available for domestic investment. A particular time sequence of $\{\Phi_t\}$ foreign saving constitutes an *indebtedness policy* in the context of the model.

In Figure 2, $s^{p_t^*}$ and $s_t^{g^*}$ represent then total (domestic plus foreign) savings — i. e. they include the effects of adding foreign savings to domestic savings s^g and s^p (see eqs. 8 to 10 in Appendix A).

To recapitulate. The model simulates the reproduction of the economic system trough time under different policy assumptions. Starting from a given initial situation, the model describes the evolution of the economy under different policy sequences. Given: (a) initial output values, (b) values of model parameters and exogenous variables, and (c) policy parameter sequences for investment policy $\{z^g_t\}$, income distribution policy $\{V_t\}$, and indebtedness policy $\{\Phi_t\}$, the model can be recursively solved forward in time, so as to numerically determine the trajectories of sectoral outputs and other endogenous variables. Endogenous income levels (by percentiles) determine in turn poverty incidence (for a given poverty line) and other welfare indicators such as the Gini coefficient of inequality. Policy sequences $\{z^g_t\}$, $\{V_t\}$ and $\{\Phi_t\}$ can be exogenously given, or they can also be determined by optimisation of some expression of social welfare. Policy sequences are exogenously given, for instance, when past development is simulated, or when a particular strategy is tested, as in the case of the official poverty reduction strategy in the next section. In Section 4.2, the model is solved for the investment policy $\{z^g_t\}$ that minimises poverty by 2015, for given income distribution $\{V_t\}$ and indebtedness $\{\Phi_t\}$ policy sequences.

3.4. Excess demands

We have thus far described the evolution of outputs/supplies over time under different policy assumptions (total supply is composed of sectoral gross outputs x_t , and includes also sectoral import duties, transaction taxes and other indirect taxes — n-vector o_t in equation (18) below). Let us finally introduce sectoral demands, in order to enquire into the "horizontal" balance between sectoral supplies and demands. ¹⁷

Total sectoral demand is composed of: (i) intermediate demands, (ii) consumption demands, and (iii) investment demands.

¹⁶ Foreign savings add also to the external debt of the period; see equation (7) in Appendix A.

¹⁷ In Appendix A.9, a flow diagram describes the whole model, including supply/demand balances.

Intermediate demands result immediately as the product Ax_t , given the $(n \times n)$ A matrix of technical coefficients. Consumption demands by type of good or service where described in equation (16) above. Investment demands are related to investment by destination d_t through the capital coefficients $(n \times n)$ matrix H of sectoral composition by sector of origin of investments by destination.¹⁸

Then, the n-vector of sectoral excess demands q_t is the difference between sectoral supplies and demands:

$$q_{t} = x_{t} + o_{t} - Ax_{t} - c_{t}^{p} - c_{t}^{g} - Hd_{t}.$$
 (18)

When all output is internationally tradable and world prices prevail in the economy, q_t represents sectoral trade balances — positive elements are net exports and negative elements are net imports. That is, the model is aimed at depicting a small open economy, in which exogenous — and for the purposes of the analysis, fixed — relative prices are assumed to prevail. The q_t vector thus reflects the effect of the strategy on international trade specialisation. In the framework of this model, a "balanced growth path" such as the turnpike solution of Bródy's equation (3) for extended reproduction — in practice, an investment policy that minimises sectoral excess demands (in absolute value) — is one of many different possible strategies. It would be the case of a particular pattern of structural change, from certain initial specialisation profile toward a more self-sufficient economy.

4. Simulating extended reproduction strategies

The above reproduction model was first conceived for simulating alternative development strategies in Mexico (Buzaglo, 1984). The by that time current official strategy of "petrolisation," that is, of dramatically expanding production capacities in the oil sector, was compared to an alternative basic needs oriented strategy, in which agriculture and other wage goods producing sectors were developed. The basic needs strategy included also an income distribution policy which stipulated improvements in the incomes of low-income classes (agricultural day labourers, poor peasants and the urban working classes, formal and informal).

Simulation with the model showed how "petrolisation" would result in increasing imports of foodstuffs. It showed also the crucial importance of increasing investment efficiency in agriculture, especially in the case of a basic needs-based strategy.

In the Mexican study investment policies are exogenously stipulated; the planned "petrolisation" investment policy of the government is simulated, and compared with a public investment sequence in which the weight of oil-related sectors is reduced, and that of essential goods producing sectors is increased (also, the weight of investment goods producing sectors is increased in the medium term).

In Buzaglo (1991), applied to Argentina, some investment policies are obtained by optimisation, instead of being exogenously stipulated. "Living off our means," a policy slogan at a time of high indebtedness and widespread capital flight, is simulated as a strategy combining (a) an investment policy rendering trade balances (sectoral excess demands) as close to zero as possible (i.e. maximising import- and export substitution), (b) a status-quo,

14

 $^{^{18}}$ Bródy's matrix **B** is equal to our matrix *H* multiplied by incremental capital output ratios $\hat{\alpha}$ (see e.g. Dervis et al. 1982, Chapter 2).

high inequality income distribution policy, and (c) an external debt moratorium reducing the stream of future foreign dissaving. In an alternative type of optimisation, an "Ideal opening" is explored, in which investment policy searches the output pattern that maximises growth. Growth maximisation is supplemented by an advanced redistribution policy, and a status-quo, non moratorium indebtedness policy.

The present study explores the viability for Bolivia of achieving the Millennium Development Goal of halving extreme poverty by 2015, and the effects that this would imply for the socioeconomy, in particular for the different social classes. Optimisation is used in the selection of both investment and income distribution policies. Investment policies are determined such as to induce poverty minimising (and for comparison, employment maximising) structural change and growth. A complementary income distribution policy is explored, which would be needed in order to achieve the goal of halving extreme poverty by 2015 — for comparison, a policy totally eliminating extreme poverty is also obtained. A further difference with the previous studies, in addition to the greater detail in the public sector's accounts, is the production of annual SAMs of part of the model simulation output (see Appendix C).

All strategies share the same foreign indebtedness policy. In all cases applies the foreign debt agreement attained with international creditors in the framework of the Debt Initiative for Highly Indebted Poor Countries, which reduces the expected outflow of savings in concept of debt repayments. Poverty reduction strategies will then only differ in their investment and income distribution policies. In what follows we succinctly describe five different strategies, (a) Base scenario, (b) Millennium investment strategy, (c) two different Millennium investment plus redistribution strategies, (d) Millennium Employment strategy.

4.1. Reproducing status quo

The Base scenario is the now superseded, official Estrategia Boliviana de Reducción de la Pobreza (EBRP). The policies proposed in the former official strategy paper (Bolivia, 2001), in spite of a detailed and accurate study of the nature and causes of widespread poverty, were a mere continuation of previous policies. The natural resource intensity of the past pattern of growth, with its concentration on oil, gas and export crops, is maintained. The EBRP investment policy maintains the existing specialization and output patterns, continuing the investment policy of the past. It maintains the focus of the past pattern of growth in capital intensive, primary sectors such as gas, oil, minerals and soybeans, and in general, it maintains the pattern of sectoral priorities of the past.

The EBRP had no statements of policies addressing the highly unequal distribution of resources and incomes. Tax policy, a key instrument of redistribution policy and an indicator of distributional preferences, was not to be activated as an instrument for poverty reduction. The simulated EBRP distribution policy is then an unchanged income distribution matrix.¹⁹

Let us now breafly comment on the results of this Base, EBRP reproduction scenario. Figure 3 shows the results of the different simulations on the share of the extremely poor in total population in 2000-2015. The EBRP initial value for extreme poverty (50 percent) corresponds to the absolute poverty line of 1 US dollar a day, the threshold commonly used in international comparisons. The figure shows that under the assumptions of our model the

¹⁹ For the assumed values of investment policy $\{z^g_t\}$, distribution policy $\{V_t\}$, indebtedness policy $\{\Phi_t\}$, and other model data, see Appendix B. They are constant for 2000-2015. The model is formulated and solved within the general algebraic modelling system GAMS (see e.g. Brooke et al., 1992).

EBRP does not succeed in halving the incidence of extreme poverty by 2015. The reduction in the share of the extremely poor is 5 percentage points, that is, 20 points below the goal.

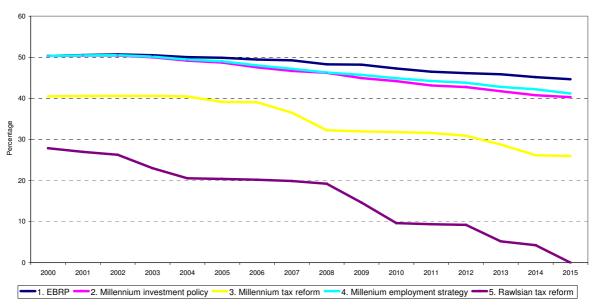

Fig. 3. Share of the population in extreme poverty

The simulated effects of the EBRP strategy on sectoral outputs are shown in Figure 4. The status-quo investment policy of the EBRP induces continued expansion of a natural resource and capital intensive sector such as Petroleum, gas and mining. This sector rapidly increases its weight in total output, although its growth rate diminishes with time. It becomes the largest sector for the most part of the period. Modern, Export crops agriculture also follows a path of rapid expansion. Food crop, traditional agriculture, on the other hand, prolongs its past stagnating trend, and its share in total output is further reduced.

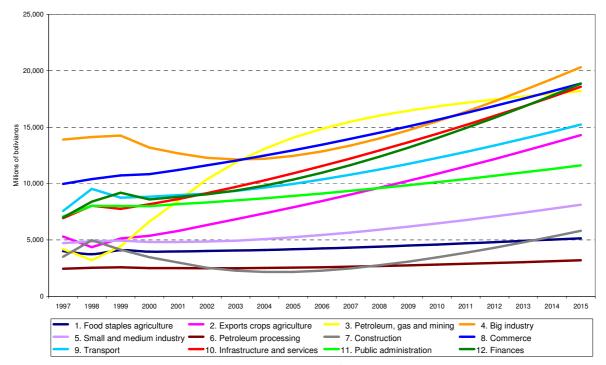

Fig. 4. Output pattern of the EBRP

In synthesis, the EBRP fails to significantly reduce poverty, due to — in addition to a low overall growth capacity — a concentrated income distribution structure, and an unhelpful sectoral growth pattern. A more helpful sectoral growth pattern, and a less concentrated income distribution structure should imply higher poverty reduction outcomes for equivalent rates of overall growth. These are the subjects of discussion of the following sections.

4.2. Poverty minimising structural change

We investigate now the possibility for investment policy alone to induce such changes in the level and structure of outputs as to reduce extreme poverty by a half by 2015. That is, we solve for the $\{z^g_t\}$ allocation vector sequence of available public investment funds — i.e. public savings available for financing the use of investment policy instruments — such that the sectoral growth pattern of the economy is most effective in reducing extreme poverty. In order to separately analyse the effects of investment and income distribution policies, we assume in this section a status quo distribution policy. That is, income distribution (corresponding to the latest income survey of year 2000) remains unchanged throughout the strategy horizon. The effect of this poverty minimizing 'Millennium investment policy' on the evolution of extreme poverty can be seen in Figure 3. The 'Millennium investment policy' does not succeed in halving poverty by 2015. Pro-poor structural change achieves only two fifths of the reduction in poverty needed to attain the Millennium Goal. The Millennium investment policy is twice as effective as the EBRP in reducing poverty, but it is still a bit more than halfway from the target.

The changes in output structure obtained by the Millennium investment policy are rather large (see Figure 5). In order to minimize poverty, investment policy favours sectors with more equal income distributions and/or higher dynamic (investment) efficiency. Activity sectors in which the poor account for a relatively large income share, and/or where the output response to investment is relatively high, tend to get higher weights in the investment policy vector.

_

²⁰ For simplicity, we solve for a constant $\{z_t^g\}$ sequence for the whole 2000-2015 period. A restriction is imposed on the excess demands of non-tradables' sectors (7th to 12th), so as to maintain the initial equilibria. One third of the public investment budget is allocated equally to all sectors. The resulting z^g vector is: (0.029 0.029 0.029 0.029 0.029 0.038 0.029 0.078 0.029 0.374 0.054 0.043 0.037)'.

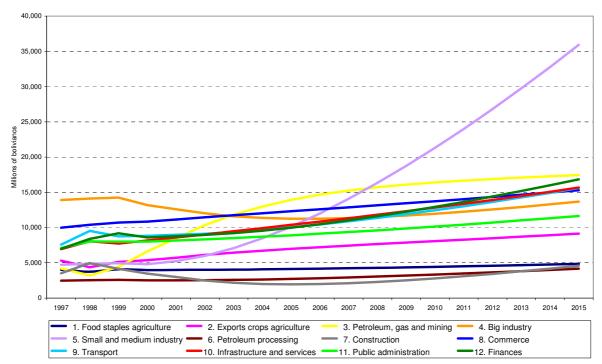

Fig. 5. Output pattern minimizing extreme poverty by 2015

Thus, sectors such as Petroleum, gas and mining, favoured by past investment policy and enjoying high growth rates, tend to gradually lose its privileged position, due to their relatively unequal distributional structure and low dynamic efficiency. Big industry, with the largest initial output share is to some extent a similar case — partially similar, as the efficiency of investment in the sector is not particularly low. Big industry loses its position of a relatively important contributor to total output, to become a more ordinary sector. Similarly, the output share of Export crops agriculture gradually declines along the period.

The Millennium investment policy favours the expansion of Small and medium industries, due to their particular income distribution structure. While this sector's investment efficiency is about the same as Big industry, its more 'pro-poor' income distribution structure makes it superior from the poverty reduction efficiency perspective, and increases its weight in investment policy. This, in turn, accelerates growth in the sector, and increases its share in total output and employment.

The case of Food staples agriculture deserves a special comment. Sustained growth of output and incomes in this sector has been singled out as the key for distributionally progressive growth. Kalecki's (1954) theoretical insights have been largely confirmed by empirical studies (see e.g. Lipton and Ravaillon, 1995). The poverty minimizing Millennium investment policy results in a disappointingly low growth for Food staples agriculture. Income distribution structure in the sector should qualify it for a high weight in investment policy — i.e., most peasants producing Food staples are poor. The problem is the sector's very low dynamic efficiency. A peso invested in Food staples agriculture gives rise to a very low increase in the sector's output — the second lowest after Transport, a very capital-intensive sector. Food staples agriculture mostly occupies very poor peasants in the highlands

_

²¹ Incremental capital output ratios α in our study were determined by historical simulation with the model, so as to track past outputs (1990-1997) as accurately as possible (see Appendix B).

(Altiplano), producing in very difficult soil and climactic conditions, and without significant infrastructure, or technical and credit support.

At any rate, present knowledge seems to suggest a careful approach to policy reform in the Food staples agricultural sector. Detailed study and experimentation should be required to arrive to effective policy reforms. Also, land tenure reform should be considered among the efficiency increasing reforms (de Janvry et al., 2001). Yet the most widely shared implication of the analyses is that agricultural policy and land reform need to be embedded in comprehensive policy and institutional reforms (de Janvry et al., 2001, p. 23).²²

The present study of optimal poverty reducing investment policies suggests also the possibility and convenience of combining agricultural reform and development with promotion of small and medium industry (and services) in rural areas. The existence of traditional, communal forms of property and production in the Altiplano highlands and other agricultural regions might resemble the conditions in the Chinese countryside two or three decades ago. The Chinese experience in recent decades shows the vast potential capacities existent in rural areas for expanding non-agricultural production. For instance, the output of China's rural industry sector increased in 1978-2000 at the astonishing rate of 22 percent per year in average (Kwong and Lee, 2005).

4.3. Expanded reproduction with structural change and income redistribution

"Let us tax the rich to subsidize the poor." Jean Paul Marat (Thompson, 1989, p. 170)

We have seen in the previous section that the poverty minimizing Millennium investment policy did not succeed in attaining the Millennium Goal of halving extreme poverty by 2015. The output structure induced by this policy implies a reduction in the poverty rate of about a half of what is needed to reach the Goal, while the Base scenario attained one tenth of the needed reduction.

Given this poverty minimising investment policy, we ask now if there are, given the consumption and saving behaviours of the different income classes in the model, viable changes in the structure of income distribution that would accomplish the remaining reduction needed. We ask if there is any $\{V_t\}$ income distribution policy sequence which along with the poverty minimising investment policy of the previous section halves extreme poverty by 2015. We design the simplest conceivable redistributive policy, consisting of a tax applied at a constant rate on all incomes above twice the poverty line (of 2 dollars a day). The fund thus collected is equally distributed to all people below the line of extreme poverty (1 dollar a day). This is of course not intended as a realistic description of what an income redistribution policy might be, but a first feasibility check of income redistribution as a means of achieving the Millennium Goal. It is also intended to roughly quantify the magnitude of the redistribution effort required.

The optimisation exercise of this section consists thus in solving the model for the income tax rate which would make the share of the extremely poor in 2015 to approach 25 percent as

²³ A realistic description of redistribution policies would also include reform policies such as asset redistributions (e.g. the already initiated land and natural resource reforms) which are not easy to quantify.

²² The government elected in 2006 has launched an ambitious land redistribution program, based primarily on the distribution among poor peasants of state, idle, and illegally occupied land.

much as it is possible — i.e. a half of what it was in 2000. The Millennium investment policy of the previous section is now supplemented by a straightforward redistribution scheme. All other things — initial conditions, behavioral coefficients and in particular, investment policy parameters — are equal to those of the previous section. The 'Millennium tax [and expenditure] reform' transforms the $\{V_t\}$ status quo income distribution into a new, post-tax and subsidies sequence $\{V_t^*\}$ which achieves the Millennium poverty goal.

Figure 3 above shows the evolution of poverty in what results to be an industrialising growth-cum-redistribution poverty reduction strategy — a poverty minimising policy focusing particularly on industrial growth based on small and medium enterprises, combined with redistributive reforms. Figure 3 shows how redistributive reforms, immediately from its inception reduce extreme poverty by 10 percentage points, and continue to progressively cut it until the Millennium Goal is attained in 2015.

The Millennium tax rate that obtains this result is 8.1 percent. A not unrealistically high rate, if it is kept in mind that, as for most Latin American countries, Bolivia's tax revenues are relatively low. Bolivia's tax revenues/GDP ratio is low in comparison to what is 'normal' given the country's level of development, that is, below the regression line relating this ratio to GDP per capita. As calculated by Perry et al. (2006, Table 5.7) Bolivia is 'undercollecting'— i.e., collecting under what would be expected given its GDP per capita level— at 3.6 percent of GDP. As a share of GDP, the Millennium tax represents 4.6 percent— the required redistribution would thus involve an additional effort of one percent of GDP above the average.

Figure 3 shows also the effects of a more ambitious, fully 'Rawlsian' strategy. A fully Rawlsian strategy would probably adopt the more ambitious goal of totally eliminating extreme poverty by 2015, giving absolute priority to the needs of the extremely poor. The 'Rawlsian tax' obtained by solving the model in exactly the same way as in the Millennium tax above — except that the objective is zero extremely poor in 2015 — is 16.7 percent.

4.4. Poverty reducing vs. employment increasing reproduction

The sectoral output elasticity of poverty, that is, the effect of sectoral growth on poverty reduction, has recently been investigated in a wide empirical study (Perry et al., 2006). According to this cross country study, relative labour intensity determines a sector's influence on poverty alleviation. Both the size of growth and the degree of labour intensity in that growth are relevant for explaining poverty reduction. '[A]griculture, the most labour-intensive sector, presents the largest growth elasticity of poverty, while mining [including oil] and utilities carry the lowest elasticities for poverty reduction' (Perry et al., 2006, p. 91).

It is interesting to check this ideas in the context of our simulation model, not only to test the empirical plausibility of the model, but also because of the potential interest of its policy inferences. The object of this section is to *ceteris paribus* compare the previous Millennium investment policy which minimises poverty, with an investment policy which induces employment maximising structural change.

In terms of our analytical model, such an employment focus is represented by the search of the investment policy that obtains the highest employment growth. In order to evaluate employment creation under different strategies, a matrix of sectoral employment coefficients by type of labour is defined, and a vector of employment by type of labour is so determined (see equation (23), Appendix A). To every output trajectory is thus associated an employment trajectory.

Hence, given the expected flows of foreign saving assumed in all strategies, and the (unchanged) initial income distribution, we solve for the investment policy $\{z_t^g\}$ that maximizes employment in the final year 2015. ²⁴

The path of extreme poverty for the Millennium employment strategy is shown in Figure 3. This strategy is slightly less effective in reducing poverty than the Millennium investment policy. It is, on the other hand, slightly more effective in expanding employment — there are about thirty thousand more occupied persons in 2015. That is, there are in general only slight differences between both strategies, and this is reflected in rather similar GDP growth rates, 4.4 percent versus 4.5 percent annually in average for the employment and poverty minimizing strategies respectively.

The small differences existing between the strategies are due to rather similar output growth patterns — the Millennium employment strategy growth pattern is shown in Figure 6. Compared to the poverty minimizing strategy, the Millennium employment strategy increases the weight of Food staples agriculture, and decreases that of Small and medium industry. ²⁵

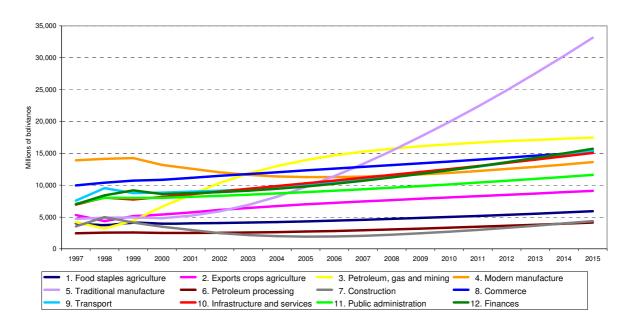

Fig. 6. Output pattern maximizing employment by 2015

Increasing the weight of Food staples agriculture in investment policy has effects on the sector's output and employment. Food staples agriculture is able to keep its share in total employment — i.e. about one fifth of the working population. Food output growth accelerates but it is still slower than population growth. Permanent excess demands of food staples make redistribution policies particularly critical, and the previous comments on agricultural reform are also pertinent here.

_

The restrictions on the $\{z_t^g\}$ investment policy vector in note 22 above apply also in this simulation. The z^g solution vector is: $(0.065\ 0.029\ 0.029\ 0.029\ 0.029\ 0.029\ 0.029\ 0.029\ 0.0368\ 0.049\ 0.044\ 0.033)$ '.

²⁵ Cf. the first and fifth elements of the corresponding investment policy z^g vectors of notes 18 and 26.

Small and medium industry is the leading sector also in the Millennium employment strategy. But a slightly diminished weight in investment policy makes growth in this sector slightly lower, as compared to the poverty minimizing strategy.

5. Poverty reduction strategies and social classes

As stated above, our reproduction model attempts to describe income distribution in detail, both in respect to the distribution of incomes according to their size, as in respect to the distribution of income among social classes. Income distribution matrix V can be seen, as the A and B input-output and capital matrices often are, as reflecting the inherent, momentary coherence structure of the socio-economy (consistent with a unique set of prices). But while input-output matrices reflect largely technical conditions, the structure of income distribution reflects mostly socio-political and historical conditions. If technological coefficients are difficult to forecast, the future configuration of social forces shaping socio-political development is even harder to guess. In our study, technical and capital coefficients were assumed to remain unchanged over time. In most simulations, income distribution coefficients were also assumed to be constant, but in two cases we tried to determine what changes in income distribution would be needed to achieve the Millennium Development Goal.

Detailed knowledge of the largely beneficial effects that halving (or eliminating) extreme poverty in the medium/long term would have for the different actors of the socio-political process should increase the probability, if any, of the necessary changes. This knowledge might also increase the selectivity of redistribution policies. It might also help to inform the basis of larger social redistributive coalitions, and to anticipate potential sources of social tension.

5.1. An approximation to poverty and class in Bolivia

Our approach to model class and poverty starts from the $(100 \times n)$ matrix of percentile income distribution by sector, which permits to identify persons/households below the poverty line. In the income redistribution simulations, the initial income distribution matrix (which corresponds to the survey year 2000) is changed into a matrix sequence that corresponds to the new (after tax and subsidies) distribution of incomes (i.e., after the simulated introduction of tax and subsidies satisfying halved (or eliminated) poverty). In order to transform the new post-redistribution $(100 \times n)$ matrix sequence of percentile income distribution by sector into a $(k \times n)$ matrix of class distribution by sector, a matrix T, formed of n matrices—a diagonal matrix of matrices—, is introduced. Each of the n matrices in the diagonal of T describes income distribution by percentiles and class in the sector. ²⁶

The source of income distribution and saving/consumption data is an extensive household survey under the Program for the Improvement of Surveys and the Measurement of Living Conditions in Latin America and the Caribbean (MECOVI) for the year 2000. The closest the MECOVI's classification of households comes to the concept of class, is the 'occupational category' — viz. (blue-collar) workers, (white-collar) employees, self-employed, employers, domestic workers. These categories, along with the rural/urban place of residence and the number of years of education (less/not less than 12 years) allow for identifying within the MECOVI household sample the following social classes: (1) urban owners, (2) rural owners, (3) skilled workers, (4) peasants, (5) non-skilled workers, and (6) self-employed.

-

²⁶ See details in Appendix A.8.

The limitations of this empirical approximation to the notion of social class are compounded by the well known problems of income data based on household surveys, among other problems the well known tendency to under-/overestimate incomes at the high/low ends of the income distribution.

Table 1. Class structure, average income, poverty and absolute poverty in Bolivia (2000)

| | Percent of | Average | Percent of | Percent in |
|-----------------|------------|----------|------------|--------------------|
| Class | households | income a | poor b | absolute poverty c |
| Urban owners | 3.7 | 2 045 | 28.1 | 12.5 |
| Rural owners | 0.4 | 2 335 | 21.1 | 20.5 |
| Skilled workers | 10.8 | 2 220 | 20.3 | 5.2 |
| Peasants | 33.2 | 309 | 93.6 | 82.1 |
| Non-skilled | 27.5 | 927 | 66.1 | 39.8 |
| workers | | | | |
| Self-employed | 24.4 | 724 | 73.3 | 45.1 |
| Total | 100.0 | 858 | 70.5 | 50.3 |

⁽a) Annual average income (dollars), (b) income under two dollars a day, (c) income under one dollar a day. Source: Household survey MECOVI 2000.

The Bolivian class structure, the level of average incomes by class, and poverty levels according to the MECOVI 2000 sample are shown in Table 1. The Bolivian class structure, more than in other Latin American societies, shows the numerical weight of the peasant class. This class is also one the most apparent actors of the process of social change and democratisation. Most of them belong to some of the different indigenous ethnic groups, work under very primitive conditions, and obtain incomes which are, in average, below the extreme poverty line of one dollar a day — by far the worst living conditions of all classes. Over three-fourths of them live in absolute poverty; very few earn incomes above the poverty line of two dollars.

The traditional working class is the second largest social class. Poverty is widespread among the non-skilled workers, but the poverty rates are much less than among peasants, and their average incomes are somewhat above the national average. The closure of tin mines and other nationalised enterprises since the mid-1980s has reduced the weight of the class. In the deindustrialising, low-growth environment of the period, this provoked a regression towards peasant agriculture (mainly coca leaf), and urban low income self-employment.

The self-employed, sometimes called the 'informal proletariat' (Portes and Hoffman, 2003), have a numerical weight similar to the working class. This is a highly heterogeneous group, which includes a wide diversity of trades and occasional employments, street vendors, and other strategies of urban survival. Many former workers of the mining, industrial and public sectors — and also many peasants escaping the miserable conditions in the countryside — became self-employed during the neoliberal 'structural adjustment' period. The average incomes of the group are about the same as the 2 dollar's poverty line, but almost half of them live in absolute poverty.

The middle class of relatively highly educated workers includes managers and administrators, and salaried professionals working in large enterprises and the public sector. The average incomes of this class are comparable to those of the propertied classes of owners, and the poverty rates are lower. The class is numerically less important than what it is in developed countries — in the US, for instance, the share of these groups is more than three times greater (see Wolff and Zacharias, 2007). But judging from their income level, their relative social and political weight is higher.

The already mentioned weaknesses of household survey data and of our own class definitions are more apparent when it comes to the numerically small capitalist class of rural and urban owners. Although the problem could have been reduced by depuration of the sample, the estimations presented here are based on rough data, and make for rather heterogeneous owner classes. The owners earn, in average, incomes that are more than twice the national average, yet there are unexpectedly large numbers of poor owners. Besides the already mentioned technical problems, this is possibly due to the very low national average, which is not far from the 2 dollar's poverty line, and that given the very diverse regional circumstances of a large poor country, ownership of a certain quantity of land or capital is not enough for escaping poverty.

5.2. *Structural change and social classes*

We have in previous sections described the effects, simulated with the help of our extended reproduction model, of five different poverty reduction strategies: Base scenario, Millennium investment strategy, two different Millennium investment plus redistribution strategies, and a Millennium employment strategy.

Our concept of strategy refers to the combination of (a) an indebtedness policy, (b) an investment policy, and (c) an income distribution policy. Indebtedness policy, which can be seen as contributing to the aim of economic policy sovereignty (as high indebtedness implies low control of own policies), is the same for all our simulated strategies — the result of the Debt Initiative for Highly Indebted Poor Countries. Investment policy, the instrument for influencing structural change, was determined, in the Base scenario, as a stipulated sequence which merely prolong past policy. In the Millennium investment strategy and the Millennium employment strategy, investment policy was determined, respectively, so as to minimise poverty, and to maximise employment. Income distribution policy, which directly affects measures of social justice — such as the Gini or other inequality indicators — is activated in two cases, in combination with poverty minimising investment policy. Instead of status quo distribution, one redistribution policy halving extreme poverty, and another eliminating it (by 2015), are obtained trough optimisation.

Table 2 shows the effects on Bolivian class structures towards 2015 for the three simulations that include different investment policies, resulting in different in different output structures in the terminal year. Given different sectoral employment- and class structures, different output structures result in different class structures.

Table 2. Class structure under different strategies, Bolivia 2015

| Class | Base scenario | Millennium investment strategy | Millennium employment strategy |
|---------------------|------------------|-----------------------------------|--------------------------------------|
| Urban owners | 3.6 | 3.7 | 3.6 |
| Rural owners | 0.4 | 0.3 | 0.3 |
| Skilled workers | 9.3 | 8.3 | 8.1 |
| Peasants | 35.2 | 28.2 | 30.7 |
| Non-skilled workers | 26.4 | 32.2 | 30.8 |
| Self-employed | 25.2 | 27.3 | 26.5 |

_

²⁷ Table 1 shows a much larger class of urban than rural owners, but this is probably due to the fact that rural owners often reside in the cities.

As we have seen in Section 4.4, the poverty minimising strategy and the employment maximising strategy result in similar output structures, and have similar effects on both poverty reduction and employment creation. As compared with the Base simulation, the Millennium strategies reduce the weight of capital intensive sectors such as natural resource and export crops sectors, which have relatively income distribution structures, and comparatively low employment intensities. Millennium strategies increase, on the other hand, the weight of more equalitarian and employment intensive sectors such as small and medium industries and services. Millennium strategies tend to increase the weight of the workers and self-employed, as compared with the Base strategy which relies more on concentrated, capital intensive sectors. Differently than in the Base strategy, the relative industrialisation stimulated by the Millennium strategies makes the share of workers surpass that of peasants in 2015.

The anti-poverty and pro-employment strategies, by reducing the output shares of capital intensive sectors with more unequal income structures, tend to diminish the weight of the middle classes of skilled workers and professionals. The Millennium strategies result in a lower weight in the social structure for the class of skilled workers.

Finally, the employment strategy, as compared with the poverty minimising one, tend as we saw before to favour the agricultural sector relatively more, and relatively less the small and

medium industry sector. The employment strategy is more pro-agrarian, with more weight for the peasant class — while in the poverty minimising strategy the weight of workers and self-employed is greater.

5.3. Poverty reduction and social classes

The focus is now on how different poverty reduction strategies may affect the different social classes. Different patterns of structural change produce different class structures, with their particular income structures. Also, income redistribution schemes as the one simulated in our study, which changes the income distribution structure by uniformly redistributing incomes towards the extremely poor, affect the classes differently. Besides its inherent interest, this kind of analysis may serve to evaluate the socio-political plausibility of different strategies, in the sense of the amplitude and weight of their potential bases of social support and resistance. It might also serve to orient specific social or sectoral policies aimed at increasing their efficacy.

Let us show the simulated effects on the incomes of the various social classes.

Urban owners. Figure 7 shows the simulated effects of the different strategies on the average income of the urban owner class. The Millennium investment and employment strategies result in similar output structures, associated in turn with similar and less unequal income distributions. These strategies rely more on 'small owner' sectors rather than on 'big owner' sectors — e.g., more of small industry and less of big industry. The resulting average incomes of the class are somewhat lower, as compared with the Base (EBRP) scenario, in which relatively more capital intensive sectors, with more concentrated ownership structures, have a greater role.

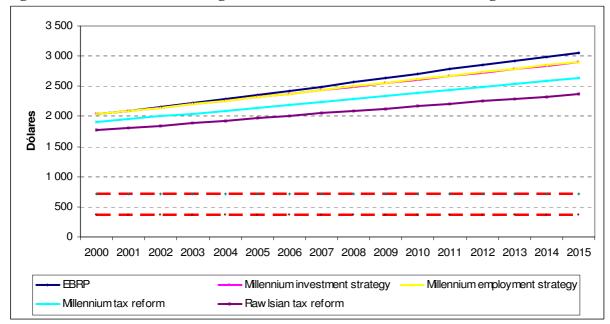

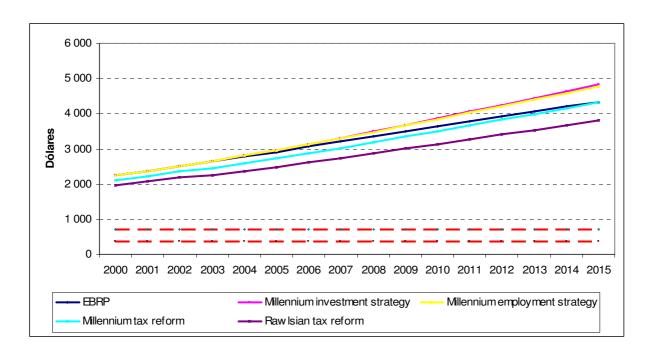

Figure 7. Urban owners. Average annual income under different strategies

The Millennium tax [and expenditure] reform strategy simulated the effects of redistribution policies needed to halve extreme poverty. These policies imply a tax of 8.1 percent on incomes above twice the poverty line of 2 dollars a day (2 and 1 dollar lines are shown in the Figure). The Rawlsian strategy, which eliminates extreme poverty in 2015, implies a tax of 16.7 percent. When introduced, redistribution policies reduce the income of the urban owners. However, income growth makes owners' average income surpass the initial, non-tax levels after a few years (two and six) in both cases.

Rural owners. This class has the highest average incomes. It has also a high number of absolute poor (see Table 1), but this most probably reflects the statistical problem of poor rural smallholders being counted as rural employers. In comparison with the case of the urban owners for whom the Base EBRP strategy gives somewhat higher incomes, for rural owners Millennium investment and employment strategies are superior strategies (Figure 8). This is due to the fact that these strategies favour investment and growth in traditional agriculture, in comparison with the Base scenario. On the basis of merely unenlightened self-interest, rural owners should also be able to favour the Millennium tax reform strategy, which combines the Millennium poverty minimising investment strategy with redistribution policies — terminal

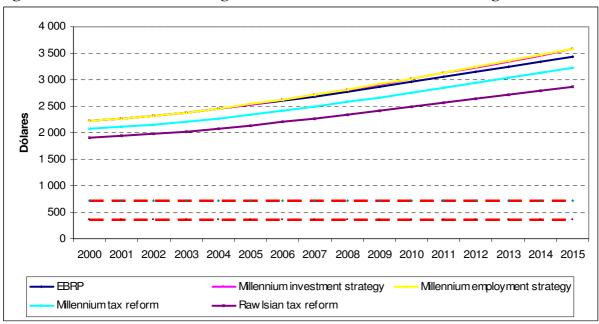

Figure 8. Rural owners. Average annual income under different strategies

average incomes are in this case about the same as in the status quo EBRP strategy. An enlightened rural owner class should even be able to support the more ambitious reform and redistribution policies of the Rawlsian strategy — the Rawlsian scenario achieves the same income levels for the class a couple of years later.

Skilled workers.

Figure 9. Skilled workers. Average annual income under different strategies

The middle classes of educated workers, managers and salaried professionals earn incomes which are in average similar to the capitalist classes. The lower incidence of absolute poverty (Table 1) indicates probably also greater homogeneity of the class and less statistical errors. As the rural owners, skilled workers would benefit of structural change of the type induced by poverty reducing and/or employment augmenting investment policies (see Figure 9). The difference with the EBRP status quo is less important, and this makes the middle classes less clear potential supporters of investment-cum-redistribution strategies.

Peasants. For its large weight in the social structure, for the widespread poverty within the class, and for the appallingly low level of their average incomes, the peasant class is the key social class in the struggle against poverty and inequality.

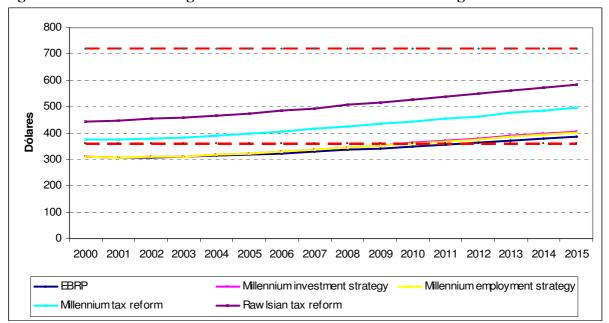

Figure 10. Peasants. Average annual income under different strategies

The results of poverty reducing (or employment increasing) investment policies on the incomes of the peasants are rather discouraging (Figure 10). Strategies which not include redistribution policies do not succeed in lifting peasants' average incomes more than a few percentage points above the extreme poverty line by 2015 — yet the investment and employment strategies cross the absolute poverty line two years before the EBRP. The already mentioned (Section 4.2) very low response to investment of output in the traditional (peasant) agricultural sector makes outputs and incomes in the sector relatively unresponsive to standard, quantitative investment policies. Ambitious, well designed and carefully implemented reforms seem to be necessary in peasant agriculture. As quoted before, 'agricultural policy and land reform need to be embedded in comprehensive policy and institutional reforms' (de Janvry et al., 2001, p. 23). At a minimum, land reform should be accompanied by infrastructural investments, agricultural research and extension, and targeted credit policies. Our simulations suggested also the convenience of combining these agricultural reform policies with the inducement of small and medium scale rural industrialisation, in imitation of the astonishing successful Chinese case.

The simulated strategies including redistribution could be understood as pessimistic interpretations of the effects of such comprehensive reform programs on the peasant class. In the very pessimistic assumption of such reforms having no effect on sectoral growth, the Millennium tax [and expenditure] reform strategy would represent the effects of an agricultural reform program of roughly 2.8 percent of GNP (as this poverty halving strategy implies a redistribution of 4.6 percent of GNP, and about 60 percent of the extremely poor are rural poor). Similarly, the Rawlsian strategy which eliminates extreme poverty by 2015 would represent the effects on the peasants' average incomes of a program for 5.7 percent of GNP.

Workers. The simulation results for the working class incomes under different strategies are somewhat paradoxical. On the one hand, structural change strategies increase the weight of the workers in the social structure (Table1). On the other hand, these strategies, increasing the weight of relatively small scale sectors that pay lower wages in average, reduces the workers' average incomes in comparison with the EBRP, which puts more weight on capital intensive high-wage sectors (Figure 11). However, the differences between the strategies are not large — EBRP average worker incomes are about 10 percent higher than the investment and employment strategies in 2015.

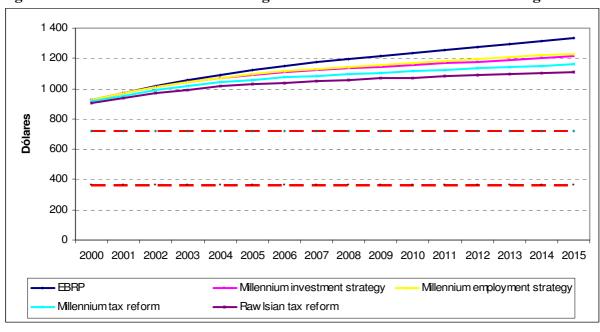

Figure 11. Non-skilled workers. Average annual income under different strategies

The workers receive wages that are in average 27 percent above the 2 dollars' poverty line, but a large proportion of them are in absolute poverty (40 percent in 2000, see Table 1). This reflects dualism and heterogeneity within the economy, but possibly also the already mentioned statistical problems. In the redistribution strategies, while workers with incomes above incomes of 4 dollars a day pay the simulated taxes, 40 percent of them are in the receiving side of the redistribution. Initially, taxes and subsidies compensate each other, but with time changes in output structure increase the differences between redistributive and non-redistributive strategies. In 2015, the Millennium tax and the Rawlsian strategy result in average incomes about 5 and 10 percent less respectively than in the investment and employment strategies. But perhaps this should not be too high a price for the working class as a whole to pay for policy changes that, from their inception, radically reduce extreme

poverty within the class — by 13 percentage points for the Millennium tax, and 26 for the Rawlsian strategy (see Figure 12) — while by 2015 it has been more than halved in one case, or totally eliminated in the other.

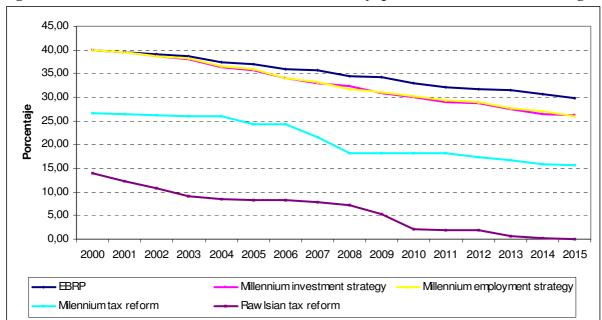

Figure 12. Non-skilled workers. Share of extremely poor under different strategies.

Self-employed. The self-employed 'informal proletariat,' is the third class in numerical import after peasants and workers (together, the three make 85 percent of the total), and after the peasant class, the class in which poverty is most prevalent (Table 1). Their average incomes are the lowest among the urban classes — roughly equal to the 2 dollars' poverty line.

Average incomes of the self-employed are more or less unchanged by different poverty reduction strategies (Figure 13). The self-employed mostly work in sectors such as commerce and construction, which grow similarly under different investment policies. The Base EBRP scenario, and the pro-poor and pro-employment investment policies affect the self-employed in similar ways.

Secondly, average incomes of the self-employed class are more or less also unchanged under different income redistribution policies under the whole period. Income dispersion and

heterogeneity within the class make that taxes paid by self-employed earning taxable incomes more or less compensate subsidies received by the large group of extremely poor.

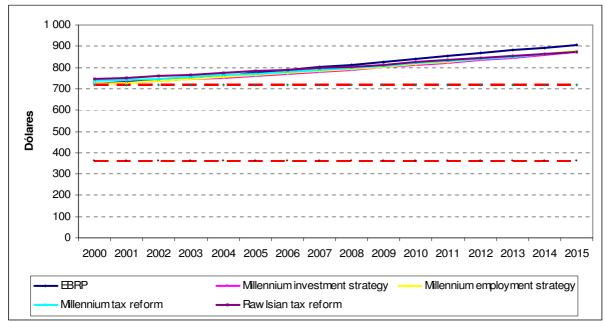

Figure 13. Self-employed. Average annual income under different strategies.

Figure 14 illustrates the neutrality of poverty among the self-employed to the simulated structural changes. EBRP and the investment strategies affect similarly the rate of extreme poverty. Only redistribution policies are successful in reducing poverty among the class of self-employed.

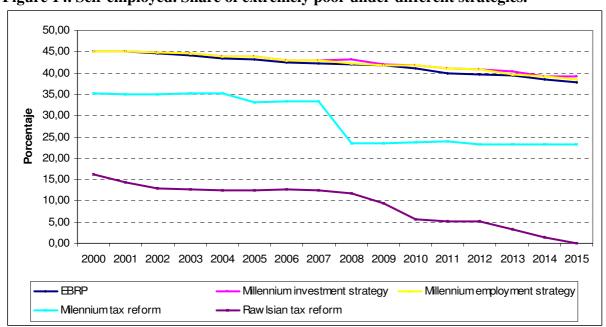

Figure 14. Self-employed. Share of extremely poor under different strategies.

Appendix A: Detailed model structure

(A flow diagram of the model is included in 9.)

1. General Notations

- *j* socioeconomic groups (percentiles)
- k socioeconomic groups (deciles)
- *n* production sectors
- t year
- on a vector transforms it in a diagonal matrix
- ' means transpose
- t vector sum (1,1,...,1)'
- I identity matrix

2. Model Parameters

Policy parameters

- z_t^g $(n \times 1)$ vector of sectoral distribution of public sector investment (sum=1)
- V_t^p (k × n) matrix of sectoral value added distribution by deciles, private sector
- V_d (1 × k) vector of coefficients of direct taxes
- V_o (1 × n) vector of sectoral coefficients of import duties, transaction tax and other indirect taxes
- V_w (1 × n) vector of sectoral coefficients of value added: wages and salaries & operating surplus of private enterprises

- V_i vector of sectoral coefficients of value added: indirect taxes and operating surplus of public enterprises
- vector of sectoral coefficients of value added: net flow of private external factors $(1 \times n)$
- $(k \times n)$ matrix of distribution of private sector value added by deciles (sum=1)
- V_{g}^{w} vector of sectoral value added distribution, public sector $(1 \times n)$
- Φ_{t} (scalar) foreign savings

Behavioral parameters

- \hat{lpha} diagonal matrix of marginal capital / output ratios $(n \times n)$
- matrix of sectoral coefficients of intermediate inputs \boldsymbol{A} $(n \times n)$
- matrix of distribution of private sector value added by percentiles (sum=1) $(j \times n)$
- matrix of distribution of the number of persons who depend on each production $(j \times n)$ sector by percentiles (sum=1)
- Γ^p matrix of marginal propensities to consume, private sector $(n \times k)$
- Н matrix of distribution by origin of investments by destination (sum=1) $(n \times n)$
- matrix of labor / output ratios Λ $(k \times n)$

3. Exogenous Variables

- (scalar) poverty line y_{pline}
- (scalar) extreme poverty line y_{eline}
- $(n \times n)$ matrix of exponential change rates in labor productivity
- (scalar) exchange rate ε
- (scalar) population growth rate r
- (scalar) interest rate (external debt) i
- R_{t} (scalar) HIPC relief
- T_t (scalar) net unilateral transfers
- (scalar) Bolivia's population

4. Endogenous Variables

- vector of gross outputs $(n \times 1)$
- x_t y^p_t $(k \times 1)$ vector of available incomes, private sector
- y^g_t public sector income (scalar)
- c^p_t vector of consumption expenditures, private sector $(n \times 1)$
- c^g_t (scalar) public sector consumption expenditure
- s^p_t vector of savings by socioeconomic group, private sector $(k \times 1)$
- s^g_t (scalar) public sector savings
- (scalar) external debt E_t
- (scalar) rate of foreign saving
- total (domestic plus foreign) private sector savings (scalar)
- $s^{g^*}t$ total (domestic plus foreign) public sector savings (scalar)
- z^p_t $(n \times 1)$ vector of sectoral distribution of private sector investment (sum=1)
- d^{p}_{t} $(n \times 1)$ vector of private sector investment by destination
- d^g_t $(n \times 1)$ vector of public sector investment by destination
- d_t $(n \times 1)$ vector of total (private plus public) investment by destination
- $(n \times 1)$ vector of total (private plus public) investment demand by sector of origin
- net flow of private external factors (wages and salaries and operating surplus) (scalar)
- f^g_t net flow of public external factors (foreign debt service) (scalar)
- vector of intermediate consumption by sector of origin (intermediate sales) $(n \times 1)$ a_t
- vector of direct taxes by socioeconomic group $(k \times 1)$ m_t

 $(n \times 1)$ vector of import duties, value added tax, non-deductible and transaction tax and o_t other indirect taxes

vector of exports net of imports by sector of origin $(n \times 1)$ q_t

 $(k \times 1)$ vector of labor requirements by socioeconomic group K_t

vector of labor requirements by production sector $(n \times 1)$ η_t

 $(n \times 1)$ vector of Bolivia's total population by production sector

 $\omega_t \\ \pi^p_t$ matrix of average per-capita income by percentile $(j \times n)$

(scalar) number of poor people

 π^{i}_{t} (scalar) number of people in absolute poverty

 σ^{p}_{t} (scalar) incidence of poverty

 σ^{i}_{t} (scalar) incidence of extreme poverty

5. Dynamic Core Equations

Private sector income

$$y^p_t = V^p x_t \tag{1}$$

Public sector income

$$y^g_t = V^g x_t + V_d y^p_t + \varepsilon T_t - \varepsilon i E_t \tag{2}$$

Private sector consumption

$$c^{p}_{t} = \Gamma^{p} \left(I - \hat{V}_{d} \right) y^{p}_{t} \tag{3}$$

Public sector consumption

$$c^g_t = x_{11t} - c^p_{11t} (4)$$

Private sector savings

$$s^{p}_{t} = \left(I - \widehat{t'}\widehat{\Gamma^{p}}\right) \left(I - \widehat{V_{d}}\right) y^{p}_{t} \tag{5}$$

Public sector savings

$$s^g_t = v^g_t - c^g_t \tag{6}$$

Foreign debt growth

$$E_{t+1} = E_t + \Phi_t - R_t \tag{7}$$

Rate of foreign saving

$$u_t = \frac{\mathcal{E}\Phi_t}{t's^p_t + s^g_t} \tag{8}$$

Private sector total (domestic plus foreign) savings

$$s^{p^*}{}_t = t' s^p{}_t (1 + u_t) \tag{9}$$

Public sector total (domestic plus foreign) savings

$$s^{g^*}{}_t = s^g{}_t (1 + u_t) \tag{10}$$

Vector of sectoral distribution of private sector investment

$$z^{p}_{t} = \frac{\hat{\alpha}(x_{t} - 0.5x_{t-1} - 0.3x_{t-2} - 0.2x_{t-3})}{t'\hat{\alpha}(x_{t} - 0.5x_{t-1} - 0.3x_{t-2} - 0.2x_{t-3})}$$
(11)

Private sector investment by sectoral destination

$$d^{p}_{t} = z^{p}_{t} s^{p^{*}}_{t} \tag{12}$$

Public sector investment by destination

$$d^{g}_{t} = z_{t}^{g} s^{g^{*}}_{t} \tag{13}$$

Total (private plus public) investment by destination

$$d_t = d^p_t + d^g_t \tag{14}$$

Output growth

$$x_{t+1} = \hat{\alpha}^{-1} d_t + x_t \tag{15}$$

6. Peripheral Equations

Total (private plus public) investment by sector of origin

$$b_t = H d_t \tag{16}$$

Net flow of private external factors

$$f_t^p = V_x x_t \tag{17}$$

Net flow of public external factors

$$f_t^g = \varepsilon i E_t \tag{18}$$

Intermediate consumption by sector of origin

$$a_t = A x_t \tag{19}$$

Direct taxes

$$m_t = \hat{V}_d y^p_t \tag{20}$$

Other taxes (import duties, value added tax, non deductible and transaction tax and other indirect taxes)

$$o_t = \hat{V}_o x_t \tag{21}$$

Exports net of imports by sector of origin

$$q_t = x_t + o_t - \left(a_t + c^p_t + c^g_t + b_t\right)$$
(22)

Employment by socio economic group

$$\kappa_t = \Lambda e^{-\hat{\tau}t} x_t \tag{23}$$

Employment by production sector

$$\eta_t = \Lambda' \hat{i} \, e^{-\hat{\tau} t} x_t \tag{24}$$

Bolivia's total population by production sector

$$\rho_t = \frac{\eta_t P_t}{\iota' \eta_t} \tag{25}$$

Average per-capita income by percentile

$$\omega_t = \frac{V_w^c x_t V_w}{V_w^{pp} \hat{\rho}_t} \tag{26}$$

Number of poor people

$$\pi^{p}_{t} = \sum_{(j,n) \in L^{p}} V_{w}^{np} \hat{\rho}_{t}(j,n) \qquad L^{p} = \left\{ (j,n) : \omega_{t}(j,n) \leq y_{pline \ (poverty \ line)} \right\}$$
(27)

Number of people in absolute poverty

$$\pi^{i}_{t} = \sum_{(j,n) \in L^{i}} V_{w}^{np} \hat{\rho}_{t}(j,n) \qquad L^{i} = \left\{ (j,n) : \omega_{t}(j,n) \leq y_{eline \ (extreme \ poverty \ line)} \right\}$$
(28)

Incidence of poverty

$$\sigma^{p}_{t} = \frac{\pi^{p}_{t}}{P_{t}} \tag{29}$$

Incidence of extreme poverty

$$\sigma^{i}_{t} = \frac{\pi^{i}_{t}}{P_{t}} \tag{30}$$

7. Accounting Identities and Auxiliary Equations

Technical coefficients plus value added coefficients add to unity

$$t' = t' A + V_w + V_i + V_x (31)$$

Vector of sectoral value added distribution, government sector

$$V^g = V_i + V_o \tag{32}$$

Matrix of sectoral value added distribution by deciles, private sector (sum=1)

$$V_w^d(k,n) = \sum_{j=l+10(k-l)}^{10k} V_w^c(j,n)$$
(33)

Matrix of sectoral value added distribution by deciles, private sector

$$V^p = V_w^d \hat{V}_w \tag{34}$$

Bolivia's population

$$P_t = P_{(0)} e^{rt} \tag{35}$$

8. From income distribution by size to income distribution by class

In order to transform the $(100 \times n)$ matrix sequence of percentile income distribution by sector reflecting progressive redistribution into a $(k \times n)$ matrix of class distribution by sector, a matrix T, composed of n matrices—a diagonal matrix of matrices—, is introduced. Each of the n matrices in the diagonal of T describes income distribution by percentiles and class in the respective sector.

Matrix T then, is formed of a diagonal of n matrices. Each of these submatrices T_i (i = 1, 2, ..., n) of T describes percentile income distribution for each of the k classes in the respective sector — i.e., their dimension is $k \times 100$.

Or, in matrix notation:
$$T = \begin{bmatrix} T_1 \\ T_2 \\ & \ddots \\ & & T_n \end{bmatrix}$$
.

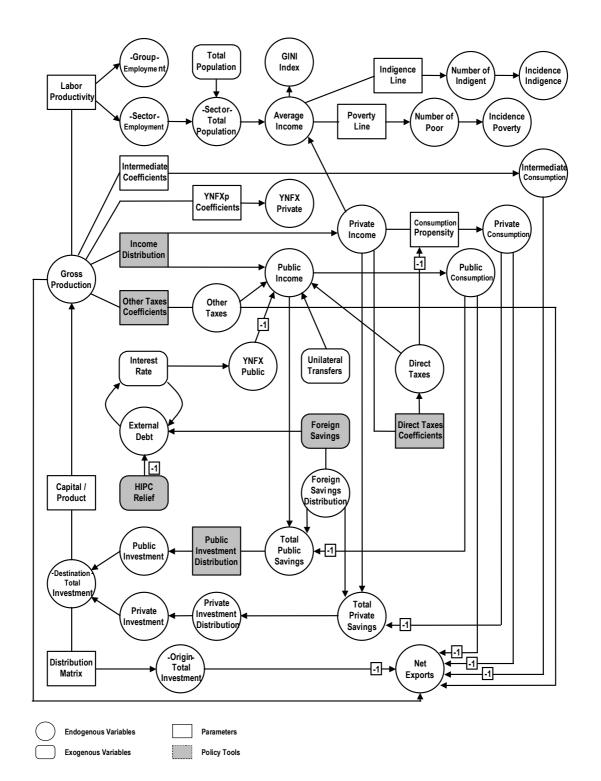

Introducing also summing vectors $t = \begin{bmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{bmatrix}$ of appropriate dimensions, along with their

transforms t' = [1, 1, ..., 1], and: $\hat{t} = \begin{bmatrix} 1 \\ 1 \\ & \ddots \\ & & 1 \end{bmatrix}$, we can define the operation:

$$\begin{bmatrix} t' & & & \\ & t' & & \\ & & \ddots & \\ & & & t' \end{bmatrix} \cdot \begin{bmatrix} T_1 & & & \\ & T_2 & & \\ & & \ddots & \\ & & & T_n \end{bmatrix} \cdot \begin{bmatrix} \hat{t} & & & \\ & \hat{t} & & \\ & & \ddots & \\ & & & \hat{t} \end{bmatrix} \cdot V = V^{class}.$$

 V^{class} is the $(k \times n)$ matrix of sectoral income distribution by social class, used for obtaining average incomes by social class.

9. Flow diagram of the detailed model

Appendix B: Model data

Sectoral aggregation key

The structural traits of the poverty problematic suggest a sectoral disaggregation that singles out those sectors in which poverty is specially concentrated, and those with particularly skewed income distributions. In the countryside, poverty is concentrated within small-scale, labor-intensive (peasant) agriculture. Export-crop, capital-intensive agriculture, should constitute a separate sector, with particular intermediate input, socioeconomic, and income distribution structures. Investment allocated to one or other of these two sectors would normally have very different effects on output, employment, exports, etc. Bolivian 36-sector national accounts distinguish between industrial agriculture, livestock, non-industrial agriculture, and coca. The two first are aggregated for the purposes of our study in an Export crops agricultural sector, and the two other in Food staples agriculture. A similar distinction is made within the urban economy. Small-scale, labor-intensive, 'informal' activities that concentrate a major share of the urban poor are described separately. The manufacturing sectors of the 36-sector Bolivian classification are aggregated into two sectors, Small and medium industry, and Big industry. The retained classification contains the following sectors: 1) Food staples agriculture, 2) Export crops agriculture, 3) Petroleum, gas, and mining, 4) Big industry, 5) Small and medium industry, 6) Petroleum processing, 7) Construction, 8) Commerce, 9) Transport, 10) Infrastructure and services, 11) Public administration, and 12) Finances.

al Sc Source: Obtained by historical optimisation with the model of the present study. Investment efficiency parameters are determined so as to make sectoral outputs generated by the model track past sectoral output trajectories (1990-1997) as accurately as possible. The problem

posed is thus to find
$$\alpha$$
 such that:
$$\sum_{1990}^{1997} (x_t - \overline{x}_t)'(x_t - \overline{x}_t) = \min,$$

in which \mathcal{X}_t and $\overline{\mathcal{X}}_t$ are simulated and historical output vectors respectively. That is, find $\boldsymbol{\mathcal{U}}$ such that the sum of the squares of the differences between the historical and the model's sectoral outputs is minimised.
